ABSTRACT

We have investigated the ram-pressure stripping of disk galaxies in clusters at various redshifts and in cluster progenitors; the clusters grow up on a hierarchical clustering scenario. We consider a radially infalling galaxy whose initial position and velocity are given by a spherical collapse model of structure formation. Moreover, since observations show that the intracluster medium (ICM) of nearby clusters is non-gravitationally heated, we study the effect of the non-gravitational heating on the ram-pressure stripping. For a given redshift, we find that ram-pressure stripping has more influence on galaxies in more massive clusters. On the other hand, for a given mass, it has more influence on galaxies in the clusters at higher redshifts. In particular, we predict that in rich clusters at $z \gtrsim 1$, most of the galaxies are affected by the ram-pressure stripping. While the non-gravitational heating significantly reduces the influence of ram-pressure stripping on galaxies in clusters with mass smaller than $1-5 \times 10^{13} M_{\odot}$, it does not affect the influence in richer clusters. If the ICM is heated non-gravitationally at $z \gg 1$, ram-pressure stripping does not occur at $z \sim 1-2$ in the progenitors of clusters observed at $0 \lesssim z \lesssim 0.5$, because the heat makes the ICM fraction of the cluster progenitors small. On the other hand, if the ICM is heated non-gravitationally at $z \sim 0$ for the first time, the ram-pressure stripping occurs even at $z \sim 3$. We compare the results with the observations of galaxies in clusters at various redshifts.

Subject headings: galaxies: clusters: general — galaxies: interactions — galaxies: ISM — galaxies: kinematics and dynamics

1. Introduction

By comparing observations of galaxies in clusters at $z \gtrsim 0.2$ with those in clusters at $z \sim 0$, we infer that some environmental effects in clusters have influences on the evolution of the galaxies. Butcher and Oemler (1978, 1984) found that clusters at $z \gtrsim 0.2$ have a high fraction of blue galaxies

in comparison with nearby clusters, and subsequent works have confirmed this trend (e.g. Lubin 1996; Rakos and Schombert 1995; Ellingson et al. 2000). Recent observations with the *Hubble Space Telescope* (HST) revealed details of the blue galaxies. Dressler et al. (1994) and Couch et al. (1998) found that most of the blue galaxies are normal spirals with active star formation. On the other hand, observations have shown that the fraction of S0 galaxies decreases rapidly with redshift in contrast with the normal spirals (Dressler et al. 1997; Smail et al. 1998; Couch et al. 1998). These suggest that the blue normal spirals observed in high redshift clusters evolve into the non-blue S0 galaxies observed in nearby clusters. In fact, observations show that in distant clusters there are galaxies in post-starburst phase (van Dokkum et al. 1998; Poggianti et al. 1999). These galaxies may be the ones for which star formation activity is dying down.

Several mechanisms are proposed that can lead to the color and morphological transformations between galaxy classes in clusters, such as galaxy mergers (Bekki 1998), tides by the cluster potential (Byrd and Valtonen 1990; Fujita 1998), and tidal interactions between galaxies (Moore et al. 1996). One of the strongest candidates is the ram-pressure stripping proposed by Gunn and Gott (1972). If a cluster galaxy moves through hot intracluster medium (ICM), it feels ram-pressure from the ICM, which is given by $\rho_{\text{ICM}} v_{\text{rel}}^2$, where ρ_{ICM} is the ICM density and v_{rel} is the relative velocity between the galaxy and the ICM. If the ram-pressure becomes large enough, the interstellar medium (ISM) of the galaxy cannot be held by the gravity of the galaxy and is swept away. Numerical simulations demonstrate that in a cluster environment, the stripping is likely to occur (Takeda, Nulsen and Fabian 1984; Gaetz, Salpeter and Shaviv 1987; Portnoy, Pistinner and Shaviv 1993; Abadi, Moore and Bower 1999; Mori and Burkert 2000). In particular, high-resolution three dimensional numerical simulations show that the ram-pressure stripping is so effective that it removes 100% of the atomic hydrogen content of luminous galaxies within 10^8 yr (Quilis, Moore and Bower 2000). On the other hand, Fujita and Nagashima (1999) investigated the influence of ram-pressure on the star formation activity of a disk galaxy. They found that just before the atomic hydrogen content is stripped, the star formation rate increases at most a factor of 2, but rapidly decreases on a timescale of 10^8 yr after the stripping. After the star formation activity, which mainly occurred in the disk, ceases, the galaxy looks like a S0 galaxy in both color and morphology (Fujita and Nagashima 1999). HI deficient galaxies and galaxies with no strong emission-lines seen in cluster cores support the theoretical predictions (e.g. Giovanelli & Haynes 1985; Dale & Uson 2000). Although ram-pressure stripping alone does not explain the detailed morphological features of S0 galaxies, such as their large bulge to disk ratios or their conspicuous thick disks (Burstein 1979a,b), it may be a principal mechanism of the transformation of spirals with active star formation into S0 galaxies with inactive star formation.

However, most of the previous studies dealt with the ram-pressure stripping of a model galaxy in a given cluster with arbitrary initial conditions. Moreover, they did not take the evolution of cluster structure into account; as will be seen in §2, the structure of high-redshift clusters is different from that of nearby clusters even for the same mass. Since it affects the ICM density, the velocity of the galaxies, and the efficiency of ram-pressure stripping, it must be considered

when we compare the theoretical models with observations of high-redshift clusters. In this paper, we investigate ram-pressure stripping in clusters at various redshifts, which grow according to a hierarchical clustering scenario; the initial position and velocity of galaxies are given by a spherical collapse model of cluster formation. Moreover, since a cluster breaks into smaller progenitors as time goes backwards, galaxies in the cluster might have been affected by ram-pressure stripping when they were in the progenitors before the present-day cluster formed. Thus, we also consider the ram-pressure stripping of galaxies in these progenitors.

Since ram-pressure is proportional to the density of ICM, the ICM distribution of a cluster may be related to the evolution of the cluster galaxies feeling ram-pressure. X-ray observations of nearby clusters show that their ICM distributions are generally different from their dark matter distributions. In particular, for low temperature clusters, the distributions of ICM are significantly flatter than those of dark matter and the ICM fraction in their central regions is small (Mohr, Mathiesen and Evrard 1999; Ettori and Fabian 1999; Arnaud and Evrard 1999). A possible explanation of the ICM distributions is that the ICM has been heated non-gravitationally. In fact, Ponman, Cannon and Navarro (1999) indicated that the entropy of the ICM in the central regions of low-temperature or less massive clusters is higher than can be explained by gravitational collapse alone, although it is not understood what heats the ICM (e.g. supernovae or AGN) and where the ICM is heated, that is, outside or inside clusters. Heating other than the gravity of a cluster makes the ICM distribution flatter and different from the dark matter distribution. Thus, we expect that the position where a galaxy suffers from ram-pressure stripping depends on whether the ICM of the cluster (or the gas accreted by the cluster later on) has been heated non-gravitationally or not. In particular, we expect that the position where ram-pressure stripping occurs is more sensitive to the non-gravitational heating in the past. This is because a cluster breaks into progenitors or less massive clusters as time goes backwards, and because the heat required to explain the observations should have more influence on the ICM distributions of the less massive clusters (Cavaliere, Menci and Tozzi 1998; Balogh, Babul and Patton 1999; Loewenstein 2000; Fujita and Takahara 2000). Therefore, ram-pressure stripping in the progenitors may tell us when the ICM of present-day clusters was heated non-gravitationally; it will be a clue to the heating sources.

Our paper is organized as follows. In §2 we describe our models of the dark matter distribution and the ICM distribution within clusters, the ram-pressure stripping of a radially infalling galaxy, and the evolution of cluster progenitors. In §3 we give the results of our calculations. We compare them with observations in §4. Conclusions are given in §5.

2. Models

2.1. Distributions of Gravitational Matter and ICM

The virial radius of a cluster with virial mass M_{vir} is defined as

$$r_{\text{vir}} = \left(\frac{3 M_{\text{vir}}}{4\pi \Delta_c(z) \rho_{\text{crit}}(z)} \right)^{1/3}, \quad (1)$$

where $\rho_{\text{crit}}(z)$ is the critical density of the universe and $\Delta_c(z)$ is the ratio of the average density of the cluster to the critical density at redshift z . The former is given by

$$\rho_{\text{crit}}(z) = \frac{\rho_{\text{crit},0} \Omega_0 (1+z)^3}{\Omega(z)}, \quad (2)$$

where $\rho_{\text{crit},0}$ is the critical density at $z = 0$, and $\Omega(z)$ is the cosmological density parameter. The latter is given by

$$\Delta_c(z) = 18 \pi^2 \quad (3)$$

for the Einstein-de Sitter Universe and

$$\Delta_c(z) = 18 \pi^2 + 82x - 39x^2, \quad (4)$$

for the flat universe with non-zero cosmological constant (Bryan and Norman 1998). In equation (4), the parameter x is given by $x = \Omega(z) - 1$.

We assume that a cluster is spherically symmetric and the density distribution of gravitational matter is

$$\rho_{\text{m}}(r) = \rho_{\text{mv}} (r/r_{\text{vir}})^{-\alpha}, \quad (5)$$

where ρ_{mv} and α are constants, and r is the distance from the cluster center. The normalization, ρ_{mv} , is given by

$$\rho_{\text{mv}} = \frac{3-\alpha}{3} \Delta_c \rho_{\text{crit}}. \quad (6)$$

We choose $\alpha = 2.4$, because the slope is consistent with observations (Horner, Mushotzky and Scharf 1999). Moreover, the results of numerical simulations show that the mass distribution in the outer region of clusters is approximately given by equation (5) with $\alpha \sim 2.4$ (Navarro, Frenk and White 1996, 1997).

We consider two ICM mass distributions. One follows equation (5) except for the normalization and the core structure;

$$\rho_{\text{ICM}}(r) = \rho_{\text{ICM,vir}} \frac{[1 + (r/r_c)^2]^{-\alpha/2}}{[1 + (r_{\text{vir}}/r_c)^2]^{-\alpha/2}}. \quad (7)$$

The ICM mass within the virial radius of a cluster is

$$M_{\text{ICM}} = \int_0^{r_{\text{vir}}} 4\pi r^2 \rho_{\text{ICM}}(r) dr. \quad (8)$$

The normalization $\rho_{\text{ICM},\text{vir}}$ is determined by the relation $f_b = M_{\text{ICM}}/M_{\text{vir}}$, where f_b is the gas or baryon fraction of the universe. This distribution corresponds to the case where the ICM is in pressure equilibrium with the gravity of the cluster and is not heated by anything other than the gravity. We introduce the core structure to avoid the divergence of gas density at $r = 0$ and use $r_c/r_{\text{vir}} = 0.1$. We call this distribution the ‘non-heated ICM distribution’. We use $f_b = 0.25(h/0.5)^{-3/2}$, where the present value of the Hubble constant is written as $H_0 = 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$. The value of f_b is the observed ICM mass fraction of high-temperature clusters (Mohr, Mathiesen and Evrard 1999; Ettori and Fabian 1999; Arnaud and Evrard 1999), for which the effect of non-gravitational heating is expected to be small.

However, as mentioned in §1, observations show that ICM is additionally heated non-gravitationally at least for nearby clusters. Thus, we also model the distribution of the heated ICM using the observed parameters of nearby clusters as follows. In this paper, we assume that the ICM had been heated before accreted by clusters. However, the distribution will qualitatively be the same even if the ICM is heated after accreted by clusters (see Loewenstein 2000).

Following Balogh, Babul and Patton (1999), we define the adiabat $K_0 = P/\rho_g^\gamma$, where P is the gas pressure, ρ_g is its density, and γ is a constant. If ICM had already been heated before accreted by a cluster, the entropy prevents the gas from collapsing into the cluster with dark matter. In this case, the ICM fraction of the cluster is given by

$$f_{\text{ICM}} = \min \left[0.040 \left(\frac{M_{\text{vir}}}{10^{14} \text{ M}_\odot} \right) \left(\frac{K_0}{K_{34}} \right)^{-3/2} \left(\frac{t(z)}{10^9 \text{ yr}} \right), f_b \right], \quad (9)$$

where $K_{34} = 10^{34} \text{ erg g}^{-5/3} \text{ cm}^2$ (Balogh, Babul and Patton 1999).

The virial temperature of a cluster is given by

$$\frac{k_B T_{\text{vir}}}{\mu m_H} = \frac{1}{2} \frac{GM_{\text{vir}}}{r_{\text{vir}}}, \quad (10)$$

where k_B is the Boltzmann constant, $\mu (= 0.61)$ is the mean molecular weight, m_H is the hydrogen mass, and G is the gravitational constant. When the virial temperature of a cluster is much larger than that of the gas accreted by the cluster, a shock forms near the virial radius of the cluster (Takizawa and Mineshige 1998; Cavaliere, Menci and Tozzi 1998). The temperature of the postshock gas (T_2) is related to that of the preshock gas (T_1) and is approximately given by

$$T_2 = T_{\text{vir}} + \frac{3}{2} T_1 \quad (11)$$

(Cavaliere, Menci and Tozzi 1998). Since the gas temperature does not change very much for $r < r_{\text{vir}}$ (Takizawa and Mineshige 1998; see also Irwin and Bregman 2000), the ICM temperature of the cluster is given by $T_{\text{ICM}} = T_2$. Since we assume that the density profile of gravitational matter is given by equation (5) with $\alpha = 2.4$, the density profile of ICM is given by

$$\rho_{\text{ICM}}(r) = \rho_{\text{ICM},\text{vir}} \frac{[1 + (r/r_c)^2]^{-3\beta/2}}{[1 + (r_{\text{vir}}/r_c)^2]^{-3\beta/2}}, \quad (12)$$

where $\beta = (2.4/3)T_{\text{vir}}/T_{\text{ICM}}$ (see Bahcall and Lubin 1994). Observations show that $T_1 \sim 0.5\text{--}1$ keV although it depends on the distribution of the gravitational matter in a cluster (Cavaliere, Menci and Tozzi 1998; Fujita and Takahara 2000). We choose $3T_1/2 = 0.8$ keV, hereafter. The normalization $\rho_{\text{ICM,vir}}$ is determined by the relation $f_{\text{ICM}} = M_{\text{ICM}}/M_{\text{vir}}$.

When $T_{\text{vir}} \lesssim (3/2)T_1$, a shock does not form but the gas accreted by a cluster adiabatically falls into the cluster. The ICM profile for $r < r_{\text{vir}}$ is obtained by solving the equation of hydrostatic equilibrium,

$$\frac{dP}{dr} = -\frac{GM(r)}{r^2}\rho_{\text{ICM}}, \quad (13)$$

where $M(r)$ is the mass of the cluster within radius r . Generally, equation (13) does not have analytical solutions for the matter distribution we adopted (equation [5] with $\alpha = 2.4$). Thus, we use the solution for the isothermal distribution ($\rho_{\text{m}}[r] = \rho_{\text{mv,iso}}[r/r_{\text{vir}}]^{-2}$) as an approximation; assuming $\gamma = 5/3$, it is given by

$$\rho_{\text{ICM}}(r) = \rho_{\text{ICM,vir}} \left[1 + \frac{3}{A} \ln \left(\frac{r_{\text{vir}}}{r} \right) \right]^{3/2}, \quad (14)$$

where

$$A = \frac{15K_0\rho_{\text{ICM,vir}}^{2/3}}{8\pi G\rho_{\text{mv,iso}}r_{\text{vir}}^2} \quad (15)$$

(Balogh, Babul and Patton 1999). The parameter $\rho_{\text{ICM,vir}}$ is determined by the relation $f_{\text{ICM}} = M_{\text{ICM}}/M_{\text{vir}}$. In §3, we use the profile (12) for $T_{\text{vir}} > 3T_1/2$ ($= 0.8$ keV) and the profile (14) for $T_{\text{vir}} < 3T_1/2$. We refer to this ICM distribution as ‘the heated ICM distribution’. From observations, we use the value of $K_0 = 0.37K_{34}$, which is assumed to be independent of cluster mass (Balogh, Babul and Patton 1999).

2.2. A Radially Infalling Galaxy

We consider a radially infalling disk galaxy accreted by a cluster with dark matter. The initial velocity of the model galaxy, v_i , is given at $r = r_{\text{vir}}$, and it is

$$\frac{v_i^2}{2} = \frac{GM_{\text{vir}}}{r_{\text{vir}}} - \frac{GM_{\text{vir}}}{r_{\text{ta}}}, \quad (16)$$

where r_{ta} is the turnaround radius of the cluster. Assuming that $r_{\text{ta}} = 2r_{\text{vir}}$ on the basis of the virial theorem, the initial velocity is

$$v_i = \sqrt{\frac{GM_{\text{vir}}}{r_{\text{vir}}}}. \quad (17)$$

The virial radius r_{vir} is given by equation (1).

The velocity of the model galaxy is obtained by solving the equation of motion;

$$\frac{d^2r}{dt^2} = -\frac{GM(r)}{r^2}. \quad (18)$$

As the velocity of the galaxy increases, the ram-pressure from ICM also increases. The condition of ram-pressure stripping is

$$\begin{aligned}
 \rho_{\text{ICM}} v_{\text{rel}}^2 &> 2\pi G \Sigma_{\star} \Sigma_{\text{HI}} \\
 &= v_{\text{rot}}^2 R^{-1} \Sigma_{\text{HI}} \\
 &= 2.1 \times 10^{-11} \text{dyn cm}^{-2} \left(\frac{v_{\text{rot}}}{220 \text{ km s}^{-1}} \right)^2 \\
 &\quad \times \left(\frac{R}{10 \text{ kpc}} \right)^{-1} \left(\frac{\Sigma_{\text{HI}}}{8 \times 10^{20} m_{\text{H}} \text{ cm}^{-2}} \right), \tag{19}
 \end{aligned}$$

where $\Sigma_{\star}$ is the gravitational surface mass density, Σ_{HI} is the surface density of the HI gas, v_{rot} is the rotation velocity, and R is the characteristic radius of the galaxy (Fujita and Nagashima 1999; Gunn and Gott 1972). Abadi, Moore and Bower (1999) have numerically confirmed that this analytic relation provides a good approximation. We define the cluster radius at which the condition (19) is satisfied for the first time as the stripping radius, r_{st} . Since we assume that the ICM is nearly in pressure equilibrium for $r < r_{\text{vir}}$, the relative velocity v_{rel} is equivalent to the velocity of the galaxy relative to the cluster for $r < r_{\text{vir}}$.

Since the mass distribution of a cluster within the virial radius does not change rapidly, the time that a galaxy takes from r_{vir} to r_{st} is approximately given by

$$\Delta t = \int_{r_{\text{st}}}^{r_{\text{vir}}} \frac{dr}{\sqrt{v_i^2 - 2\Delta\phi(r)}}, \tag{20}$$

where

$$\Delta\phi(r) = \frac{4\pi G \rho_{\text{mv}} r_{\text{vir}}^{\alpha}}{(2-\alpha)(3-\alpha)} (r^{2-\alpha} - r_{\text{vir}}^{2-\alpha}). \tag{21}$$

Thus, when the ISM of the galaxy that was located at $r = r_{\text{vir}}(t')$ at $t = t'$ is stripped at $r = r_{\text{st}}$ at $t = t' + \Delta t$, the virial radius of the cluster becomes larger than $r_{\text{vir}}(t')$.

2.3. The Growth of Clusters

We also investigate ram-pressure stripping in progenitors of a cluster. In this subsection, we construct a model of the growth of clusters.

The conditional probability that a particle which resides in a object (‘halo’) of mass M_2 at time t_2 is contained in a smaller halo of mass $M_1 \sim M_1 + dM_1$ at time t_1 ($t_1 < t_2$) is

$$P_1(M_1, t_1 | M_2, t_2) dM_1 = \frac{1}{\sqrt{2\pi}} \frac{\delta_{c1} - \delta_{c2}}{(\sigma_1^2 - \sigma_2^2)^{3/2}} \left| \frac{d\sigma_1^2}{dM_1} \right| \exp \left[\frac{(\delta_{c1} - \delta_{c2})^2}{2(\sigma_1^2 - \sigma_2^2)} \right] dM_1, \tag{22}$$

where δ_{ci} is the critical density threshold for a spherical perturbation to collapse by the time t_i , and $\sigma_i [\equiv \sigma(M_i)]$ is the rms density fluctuation smoothed over a region of mass M_i for $i = 1$ and 2

(Bond et al. 1991; Bower 1991; Lacey and Cole 1993). In this paper, we use an approximative formula of δ_{ci} (Nakamura and Suto 1997) and an fitting formula of $\sigma(M)$ for the CDM fluctuation spectrum (Kitayama 1998).

We define the typical mass of halos at t that become part of a larger halo of mass M_0 at later time $t_0(> t)$ as

$$\bar{M}(t|M_0, t_0) = \frac{\int_{M_{\min}}^{M_0} M P_1(M, t|M_0, t_0) dM}{\int_{M_{\min}}^{M_0} P_1(M, t|M_0, t_0) dM}, \quad (23)$$

where $M_{\min}$ is the lower cutoff mass. We choose $M_{\min} = 10^8 M_{\odot}$, which corresponds to the mass of dwarf galaxies.

In §3.2, we investigate a cluster progenitor whose virial mass is given by

$$M_{\text{vir}}(t|M_0, t_0) = \bar{M}(t|M_0, t_0). \quad (24)$$

In that subsection, we will often represent $M_{\text{vir}}(t|M_0, t_0)$ with $M_{\text{vir}}(t)$ or M_{vir} unless it is misunderstood, and we will often abbreviate a cluster progenitor to a ‘cluster’.

3. Results

The parameters for a model galaxy are $v_{\text{rot}} = 220 \text{ km s}^{-1}$, $R = 10 \text{ kpc}$, and $\Sigma_{\text{HI}} = 8 \times 10^{20} m_{\text{H}} \text{ cm}^{-2}$. Although the values are those for our Galaxy (Spitzer 1978; Binney and Tremaine 1987), the condition of ram-pressure stripping (relation [19]) is not much different even in the case of smaller galaxies. Taking M33 for instance, the relation (19) turns to be $\rho_{\text{ICM}} v_{\text{rel}}^2 > 2.2 \times 10^{-11} \text{ dyn cm}^{-2}$, because the values are $v_{\text{rot}} = 105 \text{ km s}^{-1}$, $R = 5 \text{ kpc}$, and $\Sigma_{\text{HI}} = 18 \times 10^{20} m_{\text{H}} \text{ cm}^{-2}$ (Newton 1980; Garnett et al. 1997; Sofue et al. 1999).

As cosmological models, we consider a standard cold dark matter model (SCDM model) and a cold dark matter model with non-zero cosmological constant (Λ CDM model). The cosmological parameters are $h = 0.5$, $\Omega_0 = 1$, $\lambda_0 \equiv \Lambda/(3H_0^2) = 0$, and $\sigma_8 = 0.63$ for the SCDM model, and $h = 0.75$, $\Omega_0 = 0.25$, $\lambda_0 = 0.75$, and $\sigma_8 = 1.0$ for the Λ CDM model. As will be seen, the results do not much depend on the cosmological models.

3.1. The Relation Between Mass and Stripping Radius

We first discuss the results of the non-heated ICM models. Figure 1 shows the relations between the stripping radius, r_{st} , and virial mass, M_{vir} , of clusters at several redshifts. For a given redshift, r_{st} is an increasing function of M_{vir} . One of the reasons is the mass-dependence of r_{vir} (Figure 2). That is, massive clusters are large. To see the effect of ram-pressure stripping, we illustrate $r_{\text{st}}/r_{\text{vir}}$ in Figure 3. For a given redshift, $r_{\text{st}}/r_{\text{vir}}$ is larger for more massive clusters. Since

not all galaxies have the pure radial orbits in real clusters, we suppose that in the real clusters with larger $r_{\text{st}}/r_{\text{vir}}$, more galaxies are affected by ram-pressure stripping. In that sense, ram-pressure stripping is more effective in more massive clusters. The mass dependence can be explicitly shown as follows. For a given redshift, the virial density of clusters, $\rho_{\text{vir}}(\equiv \Delta_c \rho_{\text{crit}})$, does not depend on mass (equations [2]-[4]). Thus, the virial radius of a cluster is given by $r_{\text{vir}} \propto (M_{\text{vir}}/\rho_{\text{vir}})^{1/3} \propto M_{\text{vir}}^{1/3}$. Therefore the velocity of a galaxy infalling into the cluster has the relation, $v_i^2 \propto M_{\text{vir}}/r_{\text{vir}} \propto M_{\text{vir}}^{2/3}$. Since the typical ICM density of a cluster is proportional to the virial density, the ram-pressure of the galaxy follows the relation, $\rho_{\text{ICM}} v_i^2 \propto M_{\text{vir}}^{2/3}$.

The virial radius, r_{vir} , of a cluster with a given mass is smaller at higher redshift (Figure 2), because the virial density of the cluster ρ_{vir} is increases as a function of redshift (equations [1]-[4]). On the other hand, r_{st} of a cluster with a given mass is larger at higher redshift in the non-heated ICM models (Figure 1). This is because the typical ICM density of clusters increases as the virial density increases. Since ram-pressure is proportional to ICM density, it is more effective at higher redshift (Figure 3). This can be clarified easily in the SCDM and non-heated ICM model as follows. The ICM density of clusters follows $\rho_{\text{ICM}} \propto \rho_{\text{vir}} \propto (1+z)^3$. For a fixed mass, the virial radius is represented by $r_{\text{vir}} \propto (M_{\text{vir}}/\rho_{\text{vir}})^{1/3} \propto (1+z)^{-1}$. Thus, the velocity of a galaxy is given by $v_i^2 \propto M_{\text{vir}}/r_{\text{vir}} \propto 1+z$, and the ram-pressure is given by $\rho_{\text{ICM}} v_i^2 \propto (1+z)^4$. This explains large $r_{\text{st}}/r_{\text{vir}}$ of high-redshift clusters (Figure 3).

Next, we show the results of the heated ICM models. In comparison with the non-heated ICM models, r_{st} and $r_{\text{st}}/r_{\text{vir}}$ for less massive clusters at a given redshift in the heated ICM models are small (Figures 1 and 3). This is because of the small ICM density of the model clusters. As the mass of clusters decreases, β in equation (12) decreases, then the ICM distribution changes from equation (12) to (14), then the ICM fraction changes from $f_{\text{ICM}} = f_{\text{b}}$ to $f_{\text{ICM}} < f_{\text{b}}$ (equation [9]). In Figures 1 and 3, the small jump at $M_{\text{vir}} = 1.3 \times 10^{14} M_{\odot}$ and $z = 0$ in the Λ CDM model is due to the shift from equation (12) to (14). Figure 3 shows that in the heated ICM model, ram-pressure stripping is ineffective for galaxy clusters (or groups) with $M_{\text{vir}} \lesssim 5 \times 10^{13} M_{\odot}$ at $z \sim 0$ and for those with $M_{\text{vir}} \lesssim 10^{13} M_{\odot}$ at $z \sim 1 - 2$. However, for rich clusters with $M_{\text{vir}} \gtrsim 10^{14} M_{\odot}$ observed at $z \sim 0.5 - 1$, the ram-pressure stripping should be more effective than the clusters with the same mass at $z \sim 0$ regardless of the non-gravitational heating.

3.2. The History of Ram-Pressure Stripping in Clusters

Using the model constructed in §2.3, we investigate the history of ram-pressure stripping of galaxies in clusters. Figure 4 shows the evolutions of $M_{\text{vir}}(t|M_0, t_0)$ for $M_0 = 2 \times 10^{15} M_{\odot}$ and $2 \times 10^{14} M_{\odot}$, that is, the evolutions of clusters with typical mass. The redshifts corresponding to t_0 are $z_0 = 0$ and 0.5. We show the evolutions of r_{vir} and r_{st} in Figures 5 and 6, respectively. At $z = z_0$, the stripping radius r_{st} in the model of the heated ICM is not much different from that in the model of the non-heated ICM. In fact, the non-gravitational heating does not affect

ram-pressure stripping for clusters with mass of $M_{\text{vir}} \gtrsim 10^{14} M_{\odot}$ at $z \sim 0$ (Figure 3). For clusters in that mass range, even if the gas had been heated before accreted by clusters, the clusters have gathered a large amount of gas and their virial temperatures have become large enough until $z = z_0$. In our model of the heated ICM, these respectively mean that $f_{\text{ICM}} = f_b$ (equation [9]) and the ICM distribution is given by equation (12). At $z = z_0$, the values of ρ_{ICM} are not much different between the heated ICM distribution and the non-heated ICM distribution at $r \sim r_{\text{st}}$, although the slope of the former distribution is smaller.

As z increases, r_{st} in the SCDM model decreases faster than that in the Λ CDM model (Figure 6). This is because M_{vir} and r_{vir} decrease faster in the former model (Figures 4 and 5). Moreover, r_{st} decreases faster in the model of the heated ICM than that in the model of the non-heated ICM. In order to see the effect of ICM heating rather than that of the decrease of cluster size, we show the evolutions of $r_{\text{st}}/r_{\text{vir}}$ in Figure 7. As can be seen, $r_{\text{st}}/r_{\text{vir}}$ decreases rapidly at high redshifts in the models of the heated ICM, while it does not change significantly in the models of the non-heated ICM. The changes of the slope in the former models are due to the shift in the ICM distribution from equation (12) to (14) and the shift in the ICM fraction from $f_{\text{ICM}} = f_b$ to $f_{\text{ICM}} < f_b$ (equation [9]). Taking the heated ICM model of $M_0 = 2 \times 10^{15} M_{\odot}$, $z_0 = 0$, and SCDM as an example (Figure 6a and 7a), the shift in the ICM distribution occurs at $z = 0.8$ and the shift in f_{ICM} occurs at $z = 1.0$. The rapid decrease of $r_{\text{st}}/r_{\text{vir}}$ in the model of the heated ICM is chiefly attributed to the decrease of f_{ICM} . On the other hand, the almost constant $r_{\text{st}}/r_{\text{vir}}$ in the models of the non-heated ICM is explained by the fact that although the mass of cluster progenitors and the velocity of galaxies in them decrease with z (Figure 4), the average mass density of progenitors, ρ_{vir} , and thus the average ICM density of progenitors, $f_b \rho_{\text{vir}}$, increase (equations [2]–[4]). We take the model of $M_0 = 2 \times 10^{15} M_{\odot}$, $z_0 = 0$, and SCDM as an example again. Figures 4 and 5 respectively show that $M_{\text{vir}} \propto (1+z)^{-6}$ and $r_{\text{vir}} \propto (1+z)^{-3}$. Thus, the velocity of the model galaxy has the redshift dependence such as $v_i^2 \propto M_{\text{vir}}/r_{\text{vir}} \propto (1+z)^{-3}$. On the other hand, $\rho_{\text{ICM}} \propto \rho_{\text{vir}} \propto (1+z)^3$. Therefore, the ram-pressure is almost independent of redshift or $\rho_{\text{ICM}} v_i^2 \propto \text{constant}$.

In summary, Figure 7 shows that if the ICM (or the gas accreted by a cluster later on) is heated non-gravitationally at $z \gg 1$, ram-pressure stripping does not occur in cluster progenitors at $z \gtrsim 1 - 2$. On the other hand, if the ICM had not been heated non-gravitationally until $z \sim 0$, ram-pressure stripping occurs even at $z \sim 3$. The difference can be explained by the small mass of cluster progenitors. At $z \sim 1 - 2$, the masses of progenitors are $M_{\text{vir}} \lesssim 10^{13} M_{\odot}$ (Figure 4). Figure 3 shows that the non-gravitational heating significantly reduces the effect of ram-pressure at this mass range at $z \sim 1 - 2$.

4. Discussion

In the previous sections, we have modeled the ram-pressure stripping in clusters and their progenitors. In this section, we compare the results with several observations. Since the direct observation of ram-pressure stripping of galaxies, such as the observation of HI distribution in

galaxies, is difficult except for nearby clusters at present, we discuss the morphology and color of galaxies.

In §3.1, we show that the ram-pressure stripping in clusters should be more effective in more massive clusters for a given redshift (Figure 3). Edge & Stewart (1991) investigate observational data of nearby clusters ($z \lesssim 0.1$) and found that the spiral fraction decreases and the S0 fraction increases with the X-ray temperature and luminosity (see also Bahcall 1977; McHardy 1978). The clusters with high X-ray temperature and luminosity are generally massive ones (e.g. Horner, Mushotzky and Scharf 1999). Thus, the relations confirmed by Edge & Stewart (1991) are consistent with our prediction, if the ram-pressure stripping converts spiral galaxies into S0 galaxies.

Recently, clusters at $z \sim 1$ are observed in detail (Postman, Lubin and Oke 1998; Kajisawa et al. 2000). Lubin et al. (1998) observed a cluster CL 1604 + 4304 at $z = 0.90$ and found that the fraction of S0 galaxies is large. The ratio of S0 galaxies to elliptical galaxies in the cluster is 1.7 ± 0.9 , which is larger than that in intermediate redshift clusters ($z \sim 0.5$). On the contrary, the fraction of spiral galaxies is only $24^{+27}_{-24}\%$. Lubin et al. (1998) estimated that the virial mass of the cluster is $M_{\text{vir}} = 7.8^{+3.2}_{-2.1} \times 10^{14} h^{-1} M_{\odot}$, which seems to be exceptionally massive at that redshift. Our model predicts that at $z \gtrsim 1$, most of the galaxies infalling into clusters of the mass should be subject to ram-pressure stripping (Figure 3). Thus, the high S0 fraction may be due to the transformation of the field spiral galaxies by ram-pressure stripping. If this is the case, the transformation by stripping must be rapid. This is because the infall rate of field galaxies, most of which are blue spiral galaxies, increases with z (Kauffmann 1995); the ram-pressure stripping must convert rather part of the blue spiral galaxies into S0 galaxies in a short time. On the other hand, most of the galaxies in a poor cluster CL 0023 + 0423 at $z = 0.84$ are normal spiral galaxies (Lubin et al. 1998). The population suggests that the ram-pressure stripping is not effective in the cluster. Since this cluster consists of two small components of $M_{\text{vir}} = 1.0^{+0.5}_{-0.4} \times 10^{13} h^{-1} M_{\odot}$ and $2.6^{+1.6}_{-0.8} \times 10^{14} M_{\odot}$, it is qualitatively consistent with our prediction (Figure 3). More observations of galaxy groups with $M_{\text{vir}} \lesssim 3 \times 10^{13} M_{\odot}$ at $z \sim 1$ may give us information about the non-gravitational heating of ICM for $z \gtrsim 1$ (see Figure 3). However, for the quantitative comparison between the theory and the observations, we may need to use a so-called semi-analytic model of cluster formation or a numerical simulation including the effects of the galaxy infall rate, the variation of galaxy orbits, and the ram-pressure stripping.

Tanaka et al. (2000) found that UV-excess red galaxies are abundant in a rich cluster near the quasar B2 1335 + 28 at $z = 1.086$; the fraction of such galaxies is relatively small at $z \sim 0.2$ (Smail et al. 1998). Tanaka et al. (2000) estimated the Abell richness of the cluster and found that it is class one. By comparing the Abell catalogue (Abell 1958) with X-ray catalogues (e.g. Jones and Forman 1999; Mohr, Mathiesen and Evrard 1999; Ettori and Fabian 1999; Arnaud and Evrard 1999), it is shown that the ICM temperature of the class one clusters is $T_{\text{ICM}} \sim 3 - 4$ keV. If $T_{\text{ICM}} = T_{\text{vir}}$, the temperature corresponds to $M_{\text{vir}} \sim 5 - 10 \times 10^{14} M_{\odot}$ in our models. Thus, our model predicts that most of the galaxies infalling into the cluster should be subject to ram-pressure stripping (Figure 3). Since the color of the UV-excess red galaxies can be explained by the superposition of

very weak star formation activity on old stellar population, the galaxies may be the ones suffering from ram-pressure stripping and the very weak star formation may be an alternative interpretation. If this is true, the abundance of the galaxies may also indicate that ram-pressure stripping happens very often at $z \sim 1$, although more sophisticated models are required for quantitative arguments as is the case of CL 1604 + 4304 and CL 0023 + 0423. In the future, it will be useful to investigate the morphology of the UV-excess red galaxies in high-redshift clusters in order to know whether the galaxies are the ones subject to ram-pressure stripping; if the galaxies have red disks, they are probably the ones (Fujita and Nagashima 1999). It is to be noted that in a rich cluster MS 1054-03 at $z = 0.83$, most of the spiral galaxies are red (van Dokkum et al. 2000).

At intermediate redshift $0.2 \lesssim z \lesssim 0.5$, observations show that the fraction of blue galaxies in rich clusters, f_b , is larger than that at $z \sim 0$ (Butcher and Oemler 1978, 1984). On the other hand, our model predicts that the fraction of galaxies affected by ram-pressure stripping increases with z . It seems that these contradict to each other, because the ram-pressure stripping suppresses star formation in galaxies (Fujita and Nagashima 1999). However, as is mentioned above, the infall rate of field spiral galaxies is higher at the intermediate redshift in comparison with $z \sim 0$. Thus, the increase of f_b that occurs in galaxy clusters at the redshift may suggest that the effect of the increase of the infall rate overwhelms the effect of the ram-pressure stripping in snapshots of galaxy population, and that the increase of f_b is not inconsistent with our prediction; we predict that for a given mass, ram-pressure stripping at the intermediate redshift is not as effective as that at $z \sim 1$ (Figure 3). Moreover, the average mass of the clusters observed at the intermediate redshift is expected to be smaller than that at higher redshift ($z \sim 1$), because the clusters at the intermediate redshift are nearer to us and easier to be observed. On the other hand, observations also suggest that the star formation of the infalling galaxies are ultimately truncated in clusters at the intermediate redshift, although there is a contradiction over the way the star formation is suppressed (Poggianti et al. 1999; Balogh et al. 1999). Considering that most of the clusters observed at the intermediate redshift are fairly rich, ram-pressure stripping should be fairly effective in the clusters, although it is not as effective as that at $z \sim 1$ (Figure 3). Thus, our model appears to be consistent with the truncation of star formation. Moreover, it is qualitatively consistent with the observed transformation of spiral galaxies into S0 galaxies in rich clusters at the intermediate redshift (see §1).

Except for extremely massive clusters ($M_{\text{vir}} \gtrsim 3 \times 10^{15} M_{\odot}$), Figure 1 shows that $r_{\text{st}} \lesssim 1$ Mpc regardless of redshift z and the ICM heating. For nearby clusters at $z \sim 0$, observations show that the fraction of S0 galaxies increases at $r \lesssim 2$ Mpc (Whitmore, Gilmore and Jones 1993; Dressler et al. 1997), which appears to be larger than the prediction by our ram-pressure model if the transformation into S0 galaxies is due to ram-pressure stripping. Moreover, for clusters observed at $0.2 \lesssim z \lesssim 0.5$, the fraction of blue galaxies also decreases at $r \lesssim 2$ Mpc (Abraham et al. 1996; van Dokkum et al. 1998; Morris et al. 1998; Kodama and Bower 2000). If ram-pressure stripping is the main mechanism of the transformation of blue spiral galaxies into S0 galaxies, the observations

suggest that some galaxies at $r \gtrsim 1$ Mpc have already been affected by the stripping when they were in the progenitors of the clusters before accreted by the main cluster progenitors. In fact, Figure 7 shows that the ram-pressure stripping in progenitors is effective at least for $z \lesssim 3$ if the ICM is not heated non-gravitationally and it is effective for $z \lesssim 1-2$ even if the ICM is heated non-gravitationally. Moreover, even if galaxies were inside the stripping radius of the main progenitor at some earlier time, some of them may have been scattered to large apocenter orbits during the merger process of cluster progenitors (Fujita et al. 1999; Balogh, Navarro and Morris 2000).

Analyzing observational data of galaxies in rich clusters, Kodama and Bower (2000) investigated the star formation history of all the galaxies in the central regions of the clusters. They found that the star formation rate per galaxy mass declines more rapidly than in the field environment at $z \lesssim 1$; it suggests the truncation of star formation in most of the galaxies. This may imply that ram-pressure stripping has been effective in the clusters or in their progenitors at least for $z \lesssim 1$, because the star formation rate of galaxies should decline after the ISM, from which stars are born, is stripped. Since Figure 7 shows that the ram-pressure stripping has been effective for $z \lesssim 1$ for rich clusters regardless of the non-gravitational heating, the results of Kodama and Bower (2000) are consistent with our predictions. Unfortunately, because of large uncertainty, their results cannot constrain the star formation rate of the galaxies in the cluster progenitors for $z \gtrsim 1$. Thus, we cannot discuss the effect of the non-gravitational heating (Figure 7).

5. Conclusions

We have studied ram-pressure stripping of galaxies in clusters and their progenitors. In particular, we pay attention to its dependence on redshift and the mass of clusters. As a model galaxy, we consider a radially infalling disk galaxy; the initial position and velocity are given by a spherical collapse model of structure formation. Since X-ray observations show that the ICM of nearby clusters is heated non-gravitationally, we also investigate the effect of the heating on the ram-pressure stripping. Our main findings are the following:

1. For a given redshift, ram-pressure stripping of galaxies is more effective in more massive clusters. This is because the velocity of the radially infalling galaxy increases with the virial mass of the cluster. If ram-pressure stripping transforms spiral galaxies into S0 galaxies, our model is consistent with the observed relation between galaxy populations and cluster luminosities (or temperatures).
2. For a given mass of clusters, ram-pressure stripping of galaxies in the clusters is more effective at higher redshift. This is because the density of the intracluster medium increases with the redshift. In particular, at $z \gtrsim 1$, most of the galaxies radially infalling into the centers of rich clusters are affected by ram-pressure stripping. The relatively high fraction of S0 galaxies and the abundance of UV-excess galaxies in rich clusters at $z \sim 1$ may be due to the ram-pressure stripping.
3. The non-gravitational heating reduces the effect of ram-pressure stripping for clusters with

$M_{\text{vir}} \lesssim 5 \times 10^{13} M_{\odot}$ at $z \sim 0$ and for those with $M_{\text{vir}} \lesssim 10^{13} M_{\odot}$ at $z \sim 1$. However, for clusters with $M_{\text{vir}} \gtrsim 10^{14} M_{\odot}$, it does not have an influence on the effect of ram-pressure stripping.

4. If the ICM (or the gas accreted by a cluster later on) is heated non-gravitationally at $z \gg 1$, ram-pressure stripping does not occur in cluster progenitors at $z \gtrsim 1 - 2$, because the heat makes the ICM fraction of the cluster progenitors small. On the other hand, if the ICM had not been heated non-gravitationally until $z \sim 0$, ram-pressure stripping occurs even at $z \sim 3$.

I am grateful to T. Yamada, M. Nagashima, I. Tanaka, T. Kodama, T. Tsuchiya, and D. A. Dale for useful discussions and comments. Comments from an anonymous referee led to significant improvements in the quality of this paper.
